Property values

ABSTRACT

Does a dramatic drop in crime lead to an increase in property values? To date, the literature on how crime influences property values has focused solely within a single metropolitan area and has been limited primarily to cross-sectional analysis. In this study we exploit the dramatic, nationwide decrease in crime that occurred in the 1990s to examine the relationship between changes in crime rates and property values. To do this, we compile information on changes in property values and crime during the 1990s in nearly 3000 urban zip codes throughout the U.S. Using a fixed-effects framework as well as an instrumental variables strategy, our analysis implies a large and statistically significant association between crime and property values. The estimated elasticities of property values with respect to crime range from -0.15 to -0.35 . Furthermore, zip codes in the top decile in terms of crime reduction saw property value increases of 7–19% during the 1990s. Both the empirical analysis and a graphical analysis are suggestive that decreasing crime leads to increasing property values.

1. Introduction

Crime has traditionally been one of the great challenges facing urban areas in the United States. The direct and indirect costs of crime are tremendous. Anderson (1999) estimates that the net annual burden of crime exceeds one trillion dollars in the U.S. Direct costs include destruction of life, destruction of property, expenditures on criminal justice programs, and expenditures on private security. Indirect costs of crime include the opportunity costs of victims, criminals and prisoners, but also the fear and anxiety that salient criminal acts such as murders, vandalism, open-air drug dealing, loitering by gang members, and prostitution can impose on neighborhoods. Overall, crime can be viewed as a neighborhood disamenity. One market that captures some of these neighborhood crime disamenities is the housing market.

During the 1990s, crime dropped dramatically throughout the United States. For example, homicide rates fell by 43% and the Federal

Bureau of Investigation's (FBI) violent and property crime indexes fell by 34 and 29% respectively (Levitt (2004)). The largest improvements in crime occurred in metropolitan areas, especially in large cities. This dramatic crime drop came as a surprise. Levitt (2004) documents how leading experts were actually predicting an increase in crime even after the crime drop had begun. However, the socioeconomic fundamentals that were thought to drive crime were relatively stable over this same time period. This led Zimring (2007) to conclude his analysis of the 1990s crime drop by saying “Whatever else is now known about crime in America, the most important lesson of the 1990s was that major changes in rates of crime can happen without major changes in the social fabric (p. 206).”

This paper exploits the unique crime drop that occurred in the 1990s to examine the link between crime and property values. From a research perspective one would like to conduct an experiment that adjusts crime rates across the U.S. to establish the causal impact of crime on property values. Although this ideal experiment is obviously impossible to conduct, certain features of the 1990s crime drop make it a type of natural experiment. These features include that the drop was large and unexpected, there was substantial variation in crime decreases within and across metropolitan areas, and the socioeconomic backdrop during this time period was not changing dramatically. Because this natural experiment takes place across the entire United States, we conform our analysis to a national setting. This allows us to take a much broader perspective on the relationship between crime and property values than the existing literature on the topic. Beginning with Thaler (1978), this small literature has focused solely within a single metropolitan area and has typically relied on cross-sectional variation in crime

and property values to obtain an estimate of some of the indirect costs of crime.¹

Perhaps one of the reasons why no one has previously examined the relationship between crime and property values on a national scale is the difficulty associated with acquiring localized crime measures and corresponding information on housing prices throughout the United States. Furthermore, one must not only have crime and housing data at a local-level to exploit the crime drop that occurred in the 1990s, one must also have this data *over time*. In this project we have overcome this difficulty by compiling a comprehensive dataset of crime, property values, and socioeconomic characteristics from 1990 to 2000 at the zip code-level in nearly three thousand urban zip codes throughout the United States. The crime data comes from a combination of a commercial vendor's zip code-level estimates of crime and the FBI's Uniform Crime Reports. The housing data is also acquired from a commercial vendor who provides home price indices at the zip code-level following the [Case and Shiller \(1987\)](#) methodology. These exceptional data allow us to fully exploit the natural experiment of the crime drop during the 1990s to examine the relationship between crime and property values across the U.S.

The results we obtain indicate a strong relationship between changes in crime rates and property values although determining causality remains problematic. Using OLS, we estimate the effect of crime changes that occurred in a given zip code between 1990 and 2000 on the change in housing values that occurred over this same period. While controlling for Metropolitan Statistical Area (MSA) fixed effects, we find that a decrease in violent crime in a zip code by 100 per 10,000 of population is associated with an increase in the average housing value in that zip code by 3.4 to 4.3%. Given that the average zip code in our sample experienced a decrease of 30 violent crimes between 1990 and 2000, this result suggests an approximately one percent increase in property values for a zip code that experienced the average drop in crime relative to a zip code with no crime reduction. However, these figures mask the substantial heterogeneity that exists. The top decile of crime-reducing zip codes in our sample experienced a decrease in violent crimes of nearly 209 crimes. Thus, our model suggests an increase in housing values of 7.5–9.5% due to the reduction in crime for these select zip codes. These results are robust to the inclusion of zip code-level controls for a variety of sociodemographic changes and to variables controlling for federal programs that also occurred in the 1990s that could act as potential confounders. Results for property crime changes are even larger. Our model suggests an increase in housing values by 14.5–19.5% for the top decile of zip codes in terms of property crime reduction. Estimating the relationship between percent changes in crime (as opposed to absolute changes) allows us to estimate elasticities of housing values with respect to crime. The OLS results with sociodemographic changes imply an elasticity with respect to violent crime of -0.15 and an elasticity with respect to property crime of -0.39 .

While we argue that our results are more credible than cross-sectional evidence, it is still primarily a correlational analysis. Although using aggregate measures of property values and crime makes pinning down a causal impact nearly impossible, we take two additional steps in our investigation that may help the plausibility of our identification strategy. First, we exploit annual housing value data to present a graphical analysis of the residuals from the regressions. These residuals are broken out by the quartiles of the 1990 violent and property crime levels. The temporal movement of housing price changes illustrated in this graphical analysis is consistent with the

national trend in crime and suggests that our results are not explained by differences in pre-treatment trends. Second, we provide results from an instrumental variable (IV) procedure. We instrument changes in crime that took place in each zip code with a measure of the amount of crime that we would have expected to have taken place in that zip code based on the national crime trend. Specifically, we match each zip code to a zip code in another MSA with similar 1990 crime levels. This procedure eliminates zip code-specific changes in crime that took place over this time period (which are likely to be endogenous) by focusing solely on crime changes that were predicted by the national trend. In a first stage we can show that changes in the levels and percent of both violent and property crime that occurred between matched zip codes, are highly correlated even when including MSA fixed effects and the zip code-level controls. Our IV estimates are greater than or equal to the OLS results suggesting that the true impact of crime rates on property values may actually be higher. However, we admit that it is difficult to fully conclude that our IV estimates, that use geographic zones rather than true micro data, are identifying the causal impact of crime on property values.

The paper proceeds as follows. [Section 2](#) provides additional detail on the 1990s crime drop. [Section 3](#) describes our unique dataset that allows us to examine the crime and property value relationship. In [Section 4](#), we describe our empirical methodology and in [Section 5](#), we present the results. Finally, [Section 6](#) concludes the paper.

2. The 1990s crime drop

The drop in crime rates that occurred between 1993 and 2000 in the United States was historically unique. It provides a type of natural crime experiment that allows for an examination of the link between crime and property values. The crime drop was exceptional in several ways. First, the decrease in crime was large and swift. Second, the crime drop was unexpected. Third, the decrease in crime was largely unrelated to the underlying socioeconomic fundamentals that have been thought to be the drivers of crime fluctuations. In this section, we provide additional details on these unique aspects of the 1990s crime drop as background to our analysis on the link between crime and property values.

2.1. Size and timing of the crime drop

The drop in crime rates from about 1993 to 2000 was dramatic. It was by far the largest and swiftest decrease in crime since modern record keeping of crime rates began in the United States. Documenting this crime drop relies on data from various sources that categorize crime in different ways. Crime comes in many different flavors. However, most research focused on national trends in crime has delineated crime into three categories: (i) homicides, (ii) violent crime other than homicides, and (iii) property crime. Here we graphically illustrate these three types of crime to provide the reader with a sense as to the size and timing of the crime drop.

The most reliable source of homicide information comes from the Vital Statistics System conducted by the National Center for Health Statistics ([Wiersema et al., 2000](#)). Information on homicides is collected around the U.S. by coroners and medical examiners during the course of their death investigations. [Fig. 1A](#) shows the national trend in homicide rates per 10,000 people. As can be seen, homicides hovered at around 1 per 10,000 between 1975 and 1993 but then dropped to about .6 per 10,000 by the year 2000.²

The National Crime Victimization Survey (NCVS) administered by the Bureau of Justice Statistics provides a measure of violent crime other than homicides. This information comes from a nationally representative sample of 87,000 households. The survey collects

¹ The cross-sectional literature includes [Thaler \(1978\)](#), [Burnell \(1988\)](#), [Lynch and Rasmussen \(2001\)](#), [Bowes and Ihlanfeldt \(2001\)](#) and [Gibbons \(2004\)](#). Several recent papers have moved beyond the cross-sectional methodology by exploiting natural experiments within a metro area including: [Schwartz et al. \(2003\)](#) who looked at the crime decrease in New York City on real estate values, and [Linden and Rockoff \(2008\)](#) and [Pope \(2008\)](#) who have looked at the impact of sex offender movements on housing prices.

² There was a temporary, small jump in 2001, but this increase is fully explained by the terrorist attack on September 11, 2001.

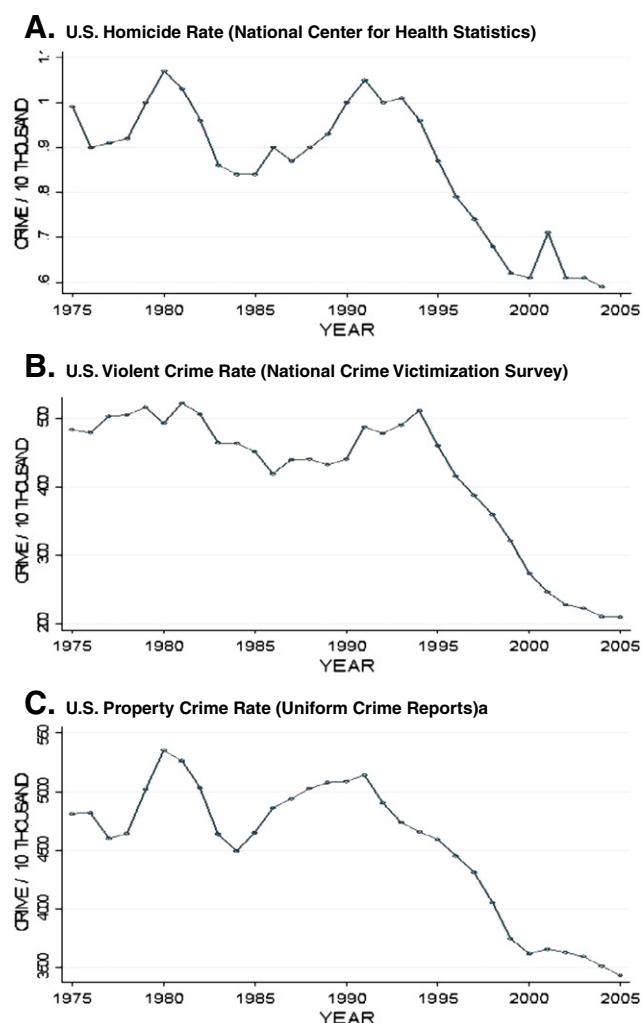

Fig. 1. U.S. Homicide, Violent Crime, and Property Crime Rate (1975–2005). Notes: Homicide, violent, and property crime rates per 10,000 population are presented in Panels A, B, and C, respectively. The series from 1975 to 2005 are presented for each crime measure. Data for each crime measure were obtained from the indicated data source in each Panel header.

information on violent crimes (excluding homicides for obvious reasons) and property crimes suffered by individuals and households. Fig. 1B shows the total violent crime per 10,000 people. The violent crimes included in the total are rape, robbery, aggravated assault and simple assault. From Fig. 1B it can be seen that the violent crime rate hovered between 450 and 500 during the 1975–1993 time period but then dropped to about 250 by the year 2000.

For a per person calculation of property crimes we turn to the Uniform Crime Reports (UCR) administered by the Federal Bureau of Investigation.³ The UCR differs from the NCVS in that if a crime is not reported to a law enforcement authority, by definition, it is excluded from the UCR. Property crimes included in the UCR are the same as the NCVS (burglary, theft, and motor vehicle theft) but are defined in a slightly different manner.⁴ Fig. 1C graphs the UCR information

³ The NCVS also calculates property crime rates but does it per household instead of per person. Since the number of households does not change at the same rate each year as the population, it makes the trends difficult to compare.

⁴ For example, the UCR defines burglary as “the unlawful entry or attempted entry of a structure to commit a felony or theft,” whereas the NCVS defines burglary as “the entry or attempted entry of a residence by a person who had no right to be there”. This is because the NCVS which relies on surveys with victims does not want victims to determine criminal motives. Another difference between the UCR and the NCVS is that commercial property crimes are included in the UCR property crimes count but not in the NCVS.

on total property crime over the same 1973 to 2005 time period used for the previous two figures. In Fig. 1C, the now familiar crime drop from 1993 to 2000 once again manifests itself. From 1975 to 1993 property crimes hovered around the 5000 per 10,000 people mark, but between 1993 and 2000 they had dropped to about 3500.⁵

Fig. 1A through C, which relies on three important crime datasets typically used to analyze crime trends, makes it clear that homicides, other violent crime, and property crime dramatically dropped from 1993 to 2000. The percentage change in the crime drop for homicides between 1993 and 2000 for the U.S. was 40%. The percentage change in violent crime as measured by the NCVS over this same time period was 44%. Property crime as measured by the UCR dropped by about 24%.

2.2. Expectations about crime before the drop

Given the swiftness of this drop and the magnitude, one would expect that crime experts would have foreseen the impending crime decrease in the early 1990s. This however was not the case. Levitt (2004) provides a nice discussion of the expectations that leading experts had in the early and middle part of the 1990s, about future crime trends. Most experts were predicting that crime would increase throughout the 1990s. One leading expert who was commissioned by the U.S. attorney general to write a report on crime trends in 1995, projected that youth homicides would rise by between 15 and 100% over the following decade even though they actually declined by approximately 50% (see Levitt 2004 for further discussion). Levitt (2004) concludes, “the crime decline was so unanticipated that it was widely dismissed as temporary or illusory long after it had begun.” (p. 170).

2.3. Relationship between the crime drop and socioeconomic fundamentals

Before the 1990s crime drop, conventional wisdom among criminologists and economists was that socioeconomic fundamentals largely drive crime changes. This notion was primarily based on cross-sectional evidence that linked crime to a variety of socioeconomic factors such as one-parent families, population instability, income inequality and the prevalence of racial minorities.⁶ However, the 1990s crime drop appears to fly in the face of this conventional wisdom. Using the 200 largest U.S. counties, Cook (2008) showed that the counties that improved in the socioeconomic characteristics that have been thought to drive crime were not much more likely to show drops in crime than other counties.

Cook (2008) concludes, “The 1990s experience – the large across-the-board reduction in crime without much progress in the socioeconomic fundamentals – is hopeful, in a way. It creates the possibility that crime rates can change dramatically, quite independently of changes in the fundamental socioeconomic conditions (p. 10).” In his comprehensive book on the subject, Zimring (2007) similarly concludes, “Whatever else is now known about crime in America, the most important lesson of the 1990s was that major changes in rates of crime can happen without major changes in the social fabric (p. 206).” According to Zimring (2007), the fact that Canada saw a similar crime drop without many of the factors that have been attributed to causing the crime drop in the U.S. occurring, means that many of the causes of the crime drop are still unclear. While far from a perfect natural experiment, the size, timing, unexpectedness, and the relative stability of the “social fabric” within the United States help to make

⁵ A similar crime drop using the UCR measures for violent crimes can be shown as well.

⁶ Examples of this cross-sectional literature include queryLand et al. (1990) and Kelly (2000).

Table 1
Summary statistics.

	1990	2000–1990		1990	2000–1990
Key variables			Control variables		
Case Shiller Index	100 (0) [0]	44.59 (36.21) [17.42]	Med. household income	42110 (14899) [12930]	14229 (12098) [11569]
Violent crime rate	336 (219) [199]	–30.01 (83.85) [81.00]	% High school grads	80.35 (11.65) [10.79]	3.31 (8.83) [8.45]
Property crime rate	3435 (1213) [1047]	–710.52 (513.07) [475.53]	% Age 0–17	24.23 (5.59) [5.26]	1.06 (4.56) [4.41]
Control variables			% Age 18–24	9.75 (4.08) [3.99]	–1.47 (3.53) [3.36]
% Unemployed	5.68 (2.03) [1.93]	–0.60 (2.93) [2.58]	% Age 25–44	34.22 (5.42) [5.02]	–2.87 (4.73) [4.59]

% Foreign nationals	4.63 (3.57) [2.73]	2.08 (3.15) [2.74]	Low income units/pop	0.048 (1.63) [1.61]	–0.011 (1.12) [1.12]
% Non-citizens	6.41 (7.93) [6.28]	2.04 (5.48) [5.24]			
			No. of MSAs	51	51
			No. of zip codes	2922	2922

Notes: Summary statistics are provided for all of the variables used in the analysis. Observations are at the zip code level. Conventional standard deviations are presented in parentheses and within-MSA standard deviations are presented in brackets. The majority of the control variables are taken from the 1990 to 2000 census (using Geolytics to allow for consistent zip-code matching). Empowerment zones, renewal community zones, and low income units per population were obtained directly from public use data provided by the Department of Housing and Urban Development.

the 1990s crime drop a type of natural crime experiment useful for this study.

3. Data

One of the reasons why no one has previously examined the relationship between crime and property values on a national scale is the difficulty in acquiring localized crime measures and corresponding information on housing prices throughout the United States. To overcome this difficulty we have compiled three datasets on crime, property values, and socioeconomic and demographic controls. Each of these datasets spans the 1990 to 2000 timeframe at the geographic scale of zip code. In this section, we describe each data type in preparation for our empirical analysis.

3.1. Crime data

The two primary sources of data on national crime that have been used by researchers in the past are the National Crime Victimization Survey (NCVS) administered by the Bureau of Justice Statistics and the Uniform Crime Reports (UCR) administered by the Federal Bureau of Investigation. As was described in Section 2, the NCVS relies on a national survey of households and is only reported at the state and national levels. Therefore, it cannot be used to look at local crime rates. The UCR data, which collects information on crimes reported to law enforcement authorities, is reported at the scale of a law enforcement authority's jurisdiction. This can be as localized as a small rural town, or as large as an entire metropolitan city serviced by a single police department. The smallest geographic level by which the UCR is consistently reported is the county level.

For our analysis we want to exploit the variation in crime that occurs within counties over time. To do this we combine information from the UCR county-level data with a dataset purchased from CAP Index, Inc. to produce measures of crime changes in 1990 and 2000 at the zip code-level. CAP Index, Inc. specializes in providing objective measures of crime for specific sites and neighborhoods.⁷ CAP Index combines data from a variety of sources including police reports, UCR data, client loss reports, and offender and victim surveys to create a “crime score,” for the same violent and property crime categories that are in the UCR at a local level.⁸ How they combine and use this information in their modeling is proprietary. CAP Index then provides a crime score index that ranges from 0 to 2000 with 100 being the average score in the United States.⁹

A difficulty with the CAP Index data from the perspective of our analysis is that comparing the crime scores across time is not straightforward. If the level of crime was reduced in all zip codes in the U.S. by the same amount over time, then the difference in the CAP Index crime scores over time would be zero. This is because the crime scores only provide relative information about zip code-level crime in the U.S. *at one point in time* (in our case the two points in time that we have are 1990 and 2000).¹⁰

⁷ CAP Index, Inc. provides crime forecasting models and loss mitigation solutions to 81 of the top U.S. Fortune 100 Companies.

⁸ CAP Index can provide property specific information. See for example Garmaise and Moskowitz (2006) who use CAP Index, Inc. data in their analysis of bank mergers and crime.

⁹ As a check on the validity of the CAP Index data relative to the more standard UCR data, we aggregate the CAP Index data to the county level and correlate this with the UCR data. The correlation between the total crime counts in the UCR and the total crime index value from CAP Index is .48 in 1990 and .46 in 2000.

¹⁰ CAP Index only updates their crime model *dienally*, and then extrapolates for each individual year. Therefore, only the 1990 and 2000 CAP Index data contains useful information for this analysis.

Homebuyers and sellers may react not only to the changes in relative crime over time, but also to changes in the levels of crime over time.

We want a zip code-level measure of crime that reflects actual crime rates as opposed to a simple index that does not account for changes in crime over time. To do this, we aggregate the CAP Index scores, weighting each zip code by its population, to the county-level for violent crimes and property crimes.¹¹ We then regress UCR violent crimes and property crimes data separately on the corresponding CAP Index crime scores (and polynomials of the crime scores) for 1990 and 2000. The resulting “crime coefficients” provide a measure of the crime levels in the UCR data that can be explained by the CAP Index crime scores. Thus, the crime coefficients can be used to weight and aggregate the CAP Index crime scores to provide an estimate of the actual crime rate in each zip code. Table 1 summarizes the resulting violent and property crime rates by zip code for the 2922 zip codes that make up our final sample. The table illustrates that the average decrease in violent and property crime that occurred in these zip codes between 1990 and 2000 was approximately 10% and 20%, respectively.¹² The standard deviations provided for these coefficients suggest that the variation in the change in crime that occurred was substantial both between and within MSAs.

3.2. Property value data

The property value data used in our analysis is Fiserv's Case-Shiller Index (CSI), produced at the zip code level. These indices are estimated using arithmetic weighting of repeat sales (Shiller, 1991) which is a variation of the Case and Shiller (1987) weighted repeat sales methodology. Housing prices of homes that have sold at least twice are collected from primarily metropolitan areas across the country. Each of these transactions has been screened to ensure that they meet criteria such as having been an arms length transaction. There are approximately 3000 zip code-level CSI's that have been consistently estimated each year from 1990 to 2000. These 3000 zip codes are found in 22 states, 51 metropolitan statistical areas (MSA), and account for approximately one fourth of the U.S. population. As can be seen in Table 1, we normalize the index such that each zip code has an index score of 100 in 1990. Between 1990 and 2000, the average increase in housing prices was about 45% with substantially more variation across MSAs relative to within MSAs. One of the advantages of this data relative to median sales price measures of changes in housing values over time (i.e. self-reported housing values given in the decennial census), is that it is not affected by the mix of properties that are sold in a given time period. Furthermore, the indexes are not affected by differences in average housing quality across zip codes. The CSI is widely considered the most accurate measure of single-family home price changes in the areas that it covers. Surprisingly, the zip code-level indices have been rarely used in academic research, and to the best of our knowledge, the full set of available zip codes has never before been used in the economics literature.¹³

3.3. Control variable data

Although according to Cook (2008), socioeconomic and sociodemographic fundamentals appear largely unrelated to the changes in crime that occurred throughout the 1990s, it still may be important to control for these factors since they may represent other urban societal shifts of importance that may have occurred over this time period. For example, some urban areas have seen gentrification occur as more affluent individuals have moved into lower-class areas. However, by including demographic information on household income, race, age and education, and information on government reinvestment efforts in our regression models, the confounding effects of this type of gentrification can be controlled for in the analysis.

Our economic and demographic information was acquired from Geolytics' “Normalized Data” product. Because census geographic boundaries often change, it can be difficult to compare census information over time. Geolytics' normalized data provides information from the 1970, 1980, and 1990 and 2000 censuses in a temporally consistent way by weighting previous census information to the 2000 census geographies. We obtained from Geolytics socioeconomic and sociodemographic information from the 1990 and 2000 censuses. We also obtained information on three Federal programs whose urban reinvestment impacts may have also been felt in the mid-1990s. These three programs were the creation of “Empowerment Zones” and “Renewal Communities” as well as the creation of additional low income housing units from the “Low Income Housing Tax Credit” program. Each of these data was obtained directly from public use data provided by the Department of Housing and Urban Development (HUD). Table 1 shows summary measures of the socioeconomic, demographic and Federal program variables used in our analysis and how they have changed over time.

4. Empirical strategy

4.1. Hedonic pricing method

The hedonic pricing method has become an important tool used by economists to estimate household valuations for local amenities such as crime. Under this method, it is argued that economic agents choose a place of residence by making informed tradeoffs between housing characteristics and various local amenities. Housing values (a measure of revealed preference) are then used to isolate the “implicit price” of a particular housing attribute or neighborhood characteristic. Early applications of this technique included attempts to understand the value of air quality (e.g. Ridker and Henning, 1967), the value of schools (e.g. Kain and Quigley, 1970), and as referenced earlier, the value of crime (e.g. Thaler, 1978).

A primary concern with the implementation of the hedonic pricing method in the housing market is omitted variable bias. Unobserved factors that are spatially correlated with the amenity of interest can lead to inconsistent estimates of implicit prices. This concern is often at its highest level when performing cross-sectional analyses. For example, in the context of crime, it is not hard to imagine that areas with high levels of crime may differ from their counterparts in labor market conditions, school quality, environmental features, and other important amenities. To the extent that these correlates of crime are not available to be controlled for in a regression analysis, estimates of the effect of crime on housing will be biased. A panel design has the potential to ameliorate the issue of omitted variable bias. The geographic fixed effects eliminate unobserved crime correlates that are time-invariant. However, to the extent that unobserved factors change at the same time as crime changes, omitted variable bias may continue to plague panel coefficient estimates.

The empirical importance of omitted variable bias in hedonic models has recently been highlighted by Black (1999), Figlio and Lucas (2004), Chay and Greenstone (2005), and Pope (2008) among

¹¹ Although homicides are a good national barometer of crime, they are rare enough at a localized level that it is difficult to use homicides as a crime indicator on its own. Therefore, we follow the convention made by others studying crime (i.e. Cullen and Levitt 1999) and focus on total violent crimes (which includes homicides) and property crimes.

¹² These percent decreases are smaller than the national decrease illustrated in Section 2. This is in large part due to the summary statistics giving equal weight to each zip code when calculating the mean crime reduction. Since, higher crime zip codes tend to have larger populations, the average over zip codes is mechanically smaller than the national average.

¹³ The only exception that we are aware of is Bui and Mayer (2003) use all the Case-Shiller zip codes for one state—Massachusetts.

others. These papers have applied quasi-random experimental procedures to urban and environmental valuation questions that likely suffer from omitted variable bias in a cross-sectional analysis. The work presented in this study builds off this literature in the construction of an identification strategy to understand the impact of crime on housing prices. Specifically, we use the variation in crime caused by the large crime decrease in the 1990s to analyze the impact of crime on housing values.

The most basic hedonic price specification that we employ takes the following form:

$$\Delta \text{CaseShillerIndex}_{ij} = \alpha + \beta(\Delta \text{CrimeRate}_{ij}) + \gamma \Delta X_{ij} + \varepsilon_{ij} \quad (1)$$

The change in the Case Shiller Index between 2000 and 1990 for each zip code i in MSA j is represented as a linear function of the change in crime rate (violent or property) that occurred in that zip code between 2000 and 1990, the change in a variety of control variables (ΔX_{ij}), and a random error term. It is worth noting again that we do not need to control for physical housing characteristics because the Case Shiller Index is based on repeat sales for homes where physical housing characteristics are differenced away.

4.2. Critiques of identification strategy

There are several critiques of the identification strategy specified by Eq. (1) that we are able to address. First, our analysis uses data across the US to identify the impact of crime on housing. The hedonic literature, however, suggests that housing markets are typically at the level of a city or smaller (see [Palmquist, 2005](#) for a discussion) suggesting that treating the country as one large housing market may be naïve. This is partially illustrated by the fact we described earlier about our data—that there is substantially more variation in property values across MSAs relative to within MSAs. Furthermore, MSA-level shocks may occur which differentially affect cities with high levels of crime relative to cities with low levels of crime. Fortunately, we have constructed a dataset with housing prices and crime at the zip code level. Thus, we have the luxury of exploiting within MSA variation. Given the importance of the MSA fixed effects in dealing with the concerns above and because they help us estimate the coefficients with much more precision, we focus on estimates that include the fixed effects.

A second critique involves the structure of the relationship between crime rate changes and housing values. As presented, this specification suggests that absolute changes in crime rates affect housing values. An alternative specification would allow for percent changes in crime rates to impact housing values. Our intuition is that using absolute changes is a more accurate model — a drop in the crime rate by 50% in a high-crime zip code in New York, for example, should have a larger impact on housing values in that zip code than a drop in the crime rate by 50% in a small town that had very little crime to begin with. However, we present results using both absolute and percent changes in crime rates for completeness.

Looking at Eq. (1), one might ask why we are doing a difference regression over a 10-year period rather than smaller time differences. While we have access to the Case Shiller Index annually, it bears repeating that we do not have *yearly* crime data at the zip-code level. Thus due to data limitations, we are unable to estimate the impact of year-to-year changes in crime rates on year-to-year changes in housing values. While our regression framework does not allow for an annual analysis, we provide graphical evidence in the next section that exploits the available, annual changes in house prices, to test for differences in pre-treatment trends, and explore how crime may affect housing prices from year-to-year. This graphical evidence helps to rule out the possibility that pre-crime trends are driving our results

and help to establish the causal link between crime changes and property value changes.

A final critique of Eq. (1) is that even with MSA fixed effects and the large drop in crime that occurred in the 1990s, this specification may still suffer omitted variable bias. Without explicit randomization, we are not able to fully address this concern. However, we can improve upon simple OLS estimates. Eq. (1) relies on two sources of variation in crime rate changes in order to identify the effect of crime on property values. The first source of variation is a result of differential impacts that the national trend in crime during the 1990s had on zip-code level crime rates (the variation we want to exploit). However, mixed in with this variation are changes in crime rates that did not occur because of the national trend (variation we want to instrument out). For example, a handful of zip codes actually experienced an increase in crime rates through the 1990s. The variation that comes from this type of crime rate change clearly has the potential to be endogenous and provides the motivation for an instrumental variables strategy.

4.3. Instrumental variables strategy

We propose an instrumental variables strategy that will help us to better isolate the variation in crime rate changes that occurred due to the national drop in crime during the 1990s. The basic intuition for this identification is that while the crime decrease during the 1990s was largely ubiquitous, certain areas were particularly affected. Specifically, high-density areas with a large amount of crime at the start of the 1990s experienced a greater decrease in crime (both in absolute and percentage terms) than their counterparts. For example, [Levitt \(2004\)](#) noted that the violent crime rates between 1991 and 2001 decreased by 36.7% within MSAs (where crime rates were initially higher) and by only 2.9% in rural areas. Thus, the drop in crime during the 1990s had a very heterogeneous effect across space.

In order to better isolate the impact of the national trend on a given zip code, we instrument each zip code's crime rate change with the crime rate change that occurred over the same period for a "similar" zip code in a different MSA. For example, the crime decrease between 2000 and 1990 that occurred in a dense, high-crime zip code in New York can be instrumented with the crime drop that occurred in a zip code in Los Angeles with similar 1990 crime levels. Thus, variation in crime rate changes that were abnormal relative to other MSAs during the 1990s is not picked up by the instrument while changes that matched the general trend are. Removing this "abnormal" variation is advantageous since zip code-specific changes in crime rates (changes that did not match the national trend) have the potential to be endogenous. For example, one source of endogeneity that has been a concern in the crime literature is mismeasurement or misreporting of crimes by local jurisdictions who face political pressures to either increase or decrease the number or reported crimes ([Baer and Chambliss, 1997](#)).¹⁴ Furthermore, crime data in general is notorious for having measurement issues. OLS estimates under a scenario of mismeasurement would be biased towards zero. Our IV strategy on the other hand does not use the zip code-specific variation in crime changes that took place during the 1990s and instead only uses the variation that can be predicted by the national trend.

The exact instrumental variables method we perform is as follows. We execute a nearest-neighbor matching algorithm that identifies for each zip code, a zip code from a different MSA that is the closest match based on 1990 total crime rates. This matching is a

¹⁴ Local police departments often have incentives to increase the reported number of crimes to support requests for more funding and/or personnel. However, local police departments can also face political pressure to show that they are effectively decreasing crime. These competing crime reporting incentives are likely to be endogenous to business and political cycles that influence property values.

Fig. 2. Relationship between change in crime rates and change in housing values (2000–1990). Notes: This figure illustrates the relationship between changes in the Case Shiller Index between 2000 and 1990 and changes in violent (Panel A and Panel C) and property (Panel B and Panel D) crimes over the same period. Each dot is an observation at the zip code level. Panels A and B graph raw changes, while Panels C and D graph the residuals from a regression of changes in the Case Shiller Index between 2000 and 1990 on year*MSA dummies.

simplification of the type of matching that has frequently been used by researchers attempting to match observations from a treatment group with a control group in order to make causal inference (Rosenbaum and Rubin, 1983; Hirano et al., 2003). Our strategy is unique in that we use the nearest neighbor match to identify the out-of-MSA candidate to serve as an instrument zip code rather than as a control zip code. Once we obtain the match for each zip code, we instrument the change in crime that occurred in a zip code with the change in crime that occurred over the same time for its matched zip code.¹⁵ While Eq. (1) provides the simplest specification that we employ, the following equation (which includes MSA fixed effects and indicates the IV strategy) is the most detailed specification in the paper:

$$\Delta \text{CaseShillerIndex}_{ij} = \alpha_i + \beta (\Delta \text{CrimeRate}_{ij}(\text{Instrumented})) + \gamma \Delta X_{ij} + \varepsilon_{ij} \quad (2)$$

A natural question is whether we would expect our instrumental variables method to increase or decrease the estimates of crime on property values relative to simple OLS. We would expect the results

to be less negative to the extent that the IV strategy eliminates endogenous crime reductions that were accompanied by zip-code specific improvements in neighborhood amenities. However, if a significant fraction of the changes in crime that occurred that did not follow the national pattern was a result of mismeasurement or misreporting of crimes, then we would expect OLS estimates to contain attenuation bias and the instrumental variables results should be larger.¹⁶ The relative incidence of endogeneity and measurement error will determine the relative size of the OLS and IV estimates.

The instrumental variables strategy as outlined above is not without flaws. Given that the identification is based on an event-study-like methodology, a key assumption is that a shock did not occur in the mid 1990s that differentially affected high and low crime areas. While we attempt to control for several potential shocks (unemployment rate changes, empowerment and renewal community zones, etc.) the absence of an unobservable shock is a necessary condition for unbiased estimation.¹⁷ So although we think our primary

¹⁵ Rather than matching solely on 1990 levels of crime, we could conceivably match zip codes on a host of 1990 census characteristics (e.g. percent black, percent unemployed, etc.). We choose to match only on 1990 crime levels for two key reasons. First, 1990 levels of crime predict better than any other variable changes in crime between 2000–1990. Thus, matching on other variables reduces the overall fit of the first stage. Second, matching on unemployment rates, population density, or other variables opens up the possibility of shocks that differentially affect certain types of zip codes to bias our estimates. Using the more parsimonious matching algorithm reduces the number of potential shocks that might affect our results.

¹⁶ See for example the discussion of the tradeoff between endogeneity and measurement error in the returns-to-education literature (Card, 2001).

¹⁷ One might argue that the economics literature has provided several potentially exogenous instruments that could be used such as lead reduction (Reyes, 2007), abortion laws (Donohue and Levitt, 2001), or drug busts (Dobkin and Nicosia, 2009). However, all of these studies provide potentially exogenous crime variation at the state-level or higher. As will be shown in the results section, because of the large changes that take place in housing prices across states and MSAs, we are only able to identify an impact of crime changes on property values when looking within an MSA. Thus, only an instrument for crime that works within an MSA could provide appropriate identification.

specification is a significant advance over a cross-sectional analysis, our results may still be based, at least partially on correlations.

5. Results

5.1. OLS results

Fig. 2A and B uses the raw data to illustrate the relationship between changes in property values and changes in violent and property crime between 2000 and 1990. It is difficult to see a relationship between housing price changes and changes in violent or property crimes when looking at both the within and between MSA variation in zip-code levels of crime and property values due to the amount of noise. Fig. 2C and D presents the relationship between changes in crime and residual changes in property values which rely exclusively on within-MSA variation, using the same axis scales. As can be seen from these figures, looking within each MSA dramatically reduces the amount of noise. Now a strong, negative relationship between the crime and property value changes can be seen which highlights the need for MSA fixed effects in our regression analysis.

A more rigorous analysis of the relationship between changes in crime and property values is presented in Table 2. Panel A provides OLS regression estimates (see Eq. (1)) of the impact of violent and property crime changes on changes in housing values. Columns (1) and (3) present the initial regression estimates with MSA fixed effects. These estimates, which indicate a negative relationship between crime changes and property value changes, are statistically significant and economically large. The coefficient in Column (2) suggests that a decrease in violent crimes by 100 per 10,000 people is

A. Violent Crime Reduction Quartiles

B. Property Crime Reduction Quartiles

Fig. 3. Annual Case Shiller Index residuals by crime reduction quartile. Notes: This figure plots year-to-year changes in residuals from a regression of the Case Shiller Index (2000–1990) on year*MSA dummies. The residuals are plotted separately for zip codes with different levels of violent (Panel A) and property (Panel B) crime reduction (2000–1990). For example, the line labeled “75th–100th percentile” represents the 25% of zip codes experiencing the largest absolute crime reduction.

associated with an increase in property values of 3.4%. The average zip code in our sample experienced a decrease in their violent crime rate by approximately 30 crimes between 1990 and 2000 suggesting an average housing price change of about 1% due to changes in violent crime over this period. However, this average masks the large amount of heterogeneity that existed in crime changes. For example, the 10% of zip codes with the largest crime decreases had an average violent crime reduction of 209 crimes per 10,000. Thus, for these zip codes, our model suggests that the decrease in crime between 1990 and 2000 resulted in an increase in housing values of nearly 7%. The coefficient estimate in Column (3) on property crimes can be interpreted in a similar way and suggests even larger results. The effect of the average zip code reduction in property crimes between 1990 and 2000 (711) is associated with a 5.6% increase in property values. The 10% of zip codes with the largest property crime reductions experienced an average increase in housing values of 14.3%.

The specifications in Columns (2) and (4) of Table 2 include zip-code level controls in addition to MSA fixed effects. The coefficient on both violent crime changes and property crime changes in these specifications are even larger in absolute value (by approximately 30%). Also, Panel B of Table 2 provides an analogous analysis to Panel A, but tests the relationship between *percent* changes in violent and property crimes on changes in housing values. Once again, we find a negative relationship between crime and housing changes that becomes even stronger when including controls at the zip-code level. The coefficient in Column (2) can be interpreted as finding that a decrease in violent crime rates by 10% results in an increase

in property values by 1.5%. Throughout the paper, we provide regression estimates using both levels and percent changes in crime. The R-squared values in Table 2 suggest that the specification in levels does a slightly better job of explaining the variation in the data. However, estimates for both specifications are informative.

In Table 2 and throughout the paper, we include violent and property crime information separately in the empirical models. Thus, the interpretation of the coefficients in these models is the impact of reducing violent (or property) crime without holding property (or violent) crime constant. These coefficients may be the most convenient for policy makers since the high correlation between violent and property crimes rarely allows for separate identification. In the Table A1 in the appendix we provide results that are analogous to Table 2, but estimate the impact of total changes of crime (violent plus property crime) together on housing values (the method used by Cullen and Levitt (1999)). Because the counts of property crimes are much higher than violent crimes, this approach relies almost solely on variation in property crimes. Thus, as expected, the estimates in Table A1 in the appendix are nearly identical to the property crime estimates in Table 2.

5.2. Dynamics of housing price changes

Using the annual Case Shiller housing data, we are able to provide a more complete picture of the results presented in Fig. 2 and Table 2 by showing the timing of the housing price changes that occurred between 1990 and 2000. To do this, we obtain housing price residuals each year by regressing the Case Shiller Index for each zip code on MSA*year dummy variables. The resulting residuals provide a representation of the unexplained change in housing prices that occurred for each year between 1990 and 2000 for each zip code. Fig. 3A and b graphs these residuals by quartiles of violent and property crime changes.

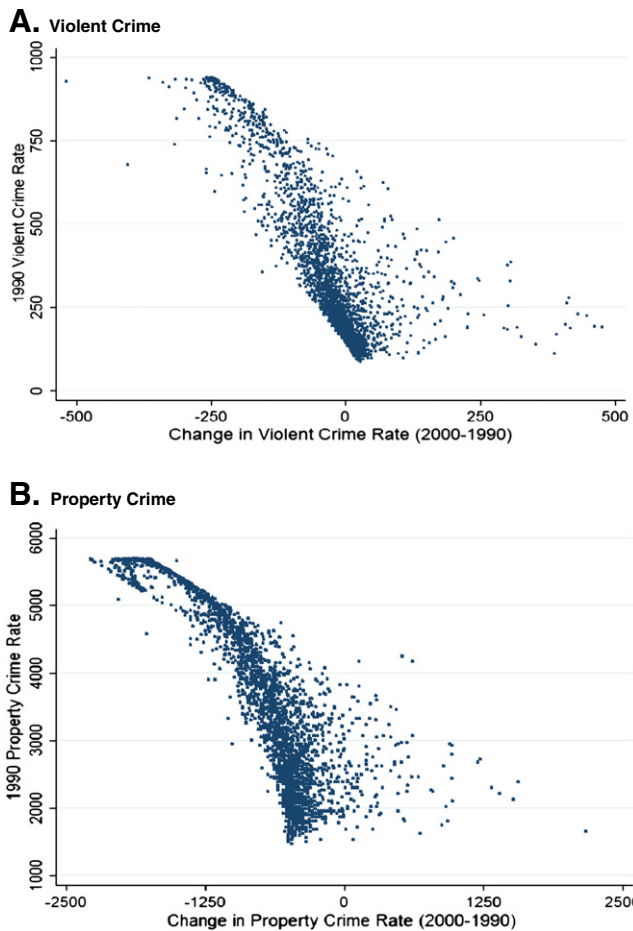

Fig. 4. Relationship between 1990 crime levels and crime changes (2000–1990). Notes: This figure illustrates the relationship between changes in violent crime (2000–1990) and 1990 violent crime levels (Panel A) and changes in property crime (2000–1990) and 1990 property crime levels (Panel B). Each dot is an observation at the zip code level.

Notes: Regression coefficients and robust standard errors are presented of the relationship between the change in the Case Shiller Index between 2000 and 1990 and changes in absolute violent and property crime (Panel A) and percent changes in violent and property crime (Panel B). Observations are at the zip-code level. Changes in violent and property crime are instrumented with changes in violent and property crime of the out-of-MSA-matched zip codes based on 1990 crime levels. All columns include MSA fixed effects for the 51 MSAs represented in the data sample. Columns (2) and (4) include all of the 2000–1990 control variables presented in Table 1.

*** Significant at 1%.

Looking at Fig. 3A, unexplained housing prices changed very little at the beginning of the 1990s between the zip codes that experienced the largest decrease in crime between 1990 and 2000 (75th–100th percentile) and zip codes that experienced the smallest decrease in crime (0–25th percentile). In fact, the change in unexplained housing values between 1990 and 1994 was essentially zero across these groups. However, starting in about 1994 and going up and through 2000, housing prices began to diverge between zip codes that experienced the largest change in crime relative to their counterparts. Similar dynamics are shown in Fig. 3B, which cuts zip codes into quartiles based on changes in property crime between 1990 and 2000. This pattern of housing price changes is very consistent with the national trend in crime that occurred.

6. IV results

We use an instrumental variable strategy discussed in Section 4.3 to estimate the impact of crime changes that are solely a result of the national trend on changes in housing values. To begin, we provide a graphical illustration of our first stage results. Panels A and B of Fig. 4 show the relationship between 1990 crime levels and crime changes (2000–1990) for violent and property crimes, respectively. The Figure illustrates that cities that had very high 1990 crime levels experienced the largest drop in crime throughout the 1990s. This is consistent with the discussion provided by Levitt (2004). This heterogeneity in crime reduction is the basis for our instrumental-variables strategy. We instrument the crime change for a given zip code with the crime change that occurred in another out-of-MSA zip code that had a similar 1990 level of crime. Fig. 4 illustrates that the first stage is likely to be very strong.

Table 3 provides the first stage results by regressing the change in crime that occurred between 1990 and 2000 for a given zip code on the change in crime that occurred in the zip code from a different matched MSA, which matching was based on 1990 crime levels. As

Notes: Regression coefficients and robust standard errors are presented of the relationship between the change in the Case Shiller Index between 2000 and 1990 and changes in absolute violent and property crime (Panel A) and percent changes in violent and property crime (Panel B). Observations are at the zip-code level. All columns include MSA fixed effects for the 51 MSAs represented in the data sample. Columns (2) and (4) include all of the 2000–1990 control variables presented in Table 1.

*** Significant at 1%.

expected, changes in crime that occurred between matched zip codes are highly correlated due to the *national* drop in crime. This is true with both violent and property crime, percent and level changes, and when including MSA fixed effects and other controls. In fact, changes in crime that occurred in a matched zip code explain anywhere from approximately 30% to 80% of the variation in crime decreases that we find suggesting that the instrument has ample statistical power.

Table 4 presents the instrumental variable results. Once again, Panel A provides the results when using absolute changes in violent and property crime while Panel B uses percent changes in crime. After controlling for MSA fixed effects, we again find a strong negative association between crime rates and property values that become even larger when including zip-code-level controls. It is informative to compare the IV results that are presented in Table 4 with the OLS results from Table 2. The IV coefficients on violent crime changes for both absolute levels and percent changes are 20–60% larger than the OLS coefficients. For property crimes, the IV coefficients are 0–10% larger. As discussed in the empirical strategy section, we attribute the increase in coefficient size to measurement error in the crime data. Using a similar interpretation of the coefficients, Column (2) of Table 4 suggests that a drop in violent crime by 100 per 10,000 people is associated with a 5.5% increase in housing values. For the 10% of zip codes with the largest violent crime reduction, we estimate that the effect of this reduction was a 12.1% increase in property values.

6.1. A robustness check

As mentioned in the empirical strategy section, the event-study research design that we employ in this paper requires that no other important, uncontrolled shock, occurred around 1994 that differentially affected high and low crime zip codes. The graphical analysis that we present as well as the robustness of our results to the

inclusion of various zip-code level controls provides some evidence that our results are more than just correlations. One worry, however, may be that changes took place in the 1990s that differentially affected zip codes with high housing values relative to zip codes with low housing values.

For example, evidence suggests that when overall housing prices increase, the distribution of housing prices also change — low-value houses increase in price by more than high-value houses (Case and Mayer, 1995). We are interested in identifying the impact of a change in crime, not a trending result based on changes in the distribution of house prices. Table 5 provides analogous results to Table 2, while controlling for the 1990 median house price value in each zip code.¹⁸ The coefficient on the 1990 median house value suggests that within MSAs, homes that had higher 1990 house values actually increased in value over the 1990s. More importantly for this analysis, we find only minor changes to the estimates of the effect of crime on housing values after adding the additional control.

7. Conclusions

This paper examines the link between crime and property values. Exploiting the dramatic, nationwide decrease in crime that occurred in the 1990s, we estimate a significant relationship between changes in crime rates and property values. The magnitude of the crime impact on property values is quite striking. The estimated elasticities of housing values with respect to crime range from -0.15 to -0.35 . These effects suggest that the top decile of zip codes in terms of crime reduction in our sample saw property value increases of 7–19% between 1990 and 2000. Our findings hold whether we use simple panel data methods, use an instrumental variables estimator, or if we control for other socioeconomic factors or government projects that also occurred in the 1990s that could act as potential confounders. The findings are also consistent for both violent and property crimes, and for whether we use changes in the levels or changes in the percent of crime as our measure of crime change. The graphical analysis of the residuals and the similarity of the IV results provide strong evidence that crime leads to increasing property values. However, because of our aggregate crime and property data and the lack of true experimental control, the findings are at least partially an interesting pattern of correlation.

Using the 1990 decennial census we calculate the average property values for the nearly 3000 zip codes used in our analysis as well as the average property values in the zip codes that are in the top decile of violent and property crime.¹⁹ Using these 1990 average property values as well as the average decline in violent crime across zip codes (approximately 30), we estimate that the crime decrease translated into an average gain of around \$2000 per house. However, in the top decile of zip codes in terms of violent crime, the average violent crime decrease was around 209. Our estimates suggest that in these zip codes, the housing price gain from decreased crime was closer to \$11,000 for each house. The average price gains were even larger when calculated looking at changes in property crime. These estimates would suggest per house property value gains of between \$11,000 for all zip codes and between \$20,000 and \$27,000 for houses in the top decile of property crime.

When estimating the benefits of crime reduction, it is important to understand the implications of the time window used in the analysis. A reduction in crime surely has an immediate benefit (people feel safer, property is less likely to be destroyed, etc.) that should be reflected in housing values. Over time the benefits from reduced

crime may continue to accrue. For example, restaurants and stores may decide to enter a neighborhood once crime has been more permanently reduced. Understanding the agglomeration effect of crime reduction is important from a policy perspective. The estimates that we find in our analysis likely include both the immediate benefit of crime reduction, and some of the benefits that can accrue from this crime reduction over a 4–6 year period.

The analysis presented in this paper is the first attempt to estimate the impact of crime on housing values at the national level. This paper also contributes to the literature on the rise and fall of urban areas and cities.²⁰ Urban areas have for many years been in decline. However, during the 1990s many urban areas have staged a comeback. Policymakers and city officials are keenly interested in the reasons for this resurgence. One factor that has been hypothesized to have contributed to the recent resurgence of urban areas was the dramatic drop in crime during the 1990s that occurred in these urban areas. The results in this paper lend support to this theory by documenting the relationship between crime and property values. Thus this work supports the view that policymakers and city officials concerned with urban growth should make crime prevention an important priority. Additional work on the relationship between city efforts to reduce crime, the role of specific crimes on property values and the magnitude of other externalities stemming from crime and its influence on property values represent exciting avenues for future research.

Appendix A

Table A1
Changes in total crime and property values (2000–1990) — OLS levels and percentages.

Panel A		
	(1)	(2)
2000–1990 Total crime diff	–0.007 (.001) ^{***}	–0.009 (.001) ^{***}
MSA fixed effects	X	X
2000–1990 Controls		X
R-squared	0.779	0.792
Observations	2922	2912
Panel B		
	(1)	(2)
2000–1990 Total crime% diff	–31.57 (3.41) ^{***}	–38.66 (3.79) ^{***}
MSA fixed effects	X	X
2000–1990 Controls		X
R-squared	0.776	0.787
Observations	2922	2912

Notes: Regression coefficients and robust standard errors are presented of the relationship between the change in the Case Shiller Index between 2000 and 1990 and changes in absolute total crime (Panel A) and percent changes in total crime (Panel B). Observations are at the zip-code level and include MSA fixed effects for all 51 MSAs represented in the data sample. Column (2) includes all of the 2000–1990 control variables presented in Table 1.

*** Significant at 1%.
